

Intercalation between Anthracyclines and DNA

First of all, consider the 3-D structure of a DNA fragment (including a solvated magnesium ion), determined by X-ray crystallography:

Alternative DNA Fragments: B-DNA fragment 1 (B-DNA-FRAGMENT.jpg), B-DNA fragment 1 view 2 (B-DNA-FRAGMENT2.jpg).

The primary mode of action of daunomycin (**1**) and Adriamycin (**2**) is believed to be their reversible binding to nucleolar DNA which causes inhibition of the replication process¹ and thence death. Numerous biochemical studies including evidence from NMR spectroscopic and X-ray crystallographic studies have shown that daunomycin and Adriamycin intercalate into the B-form of the DNA double stranded helix with guanine-cytosine d(CpG) site-specific interactions². The base pairs above and below the drug 'buckle' in conformation to afford a distorted DNA helix thereby preventing association with the DNA helicase, DNA topoisomerase³ and polymerase families of enzymes to initiate DNA replication for RNA synthesis, protein formation and thereby cell division.

i. DNA-Daunomycin Complex

As a result of intercalation with daunomycin⁴, the GC and CG base pairs 'buckle' by ca. 9° and 15° respectively to prevent excessive van der Waal's contacts. Also, the base pairs separate from a nominal distance of 3.4 Å to 6.8 Å when accommodating the drug and these distortions lead to a total DNA unwinding angle of ca. 8° (5.2 measured from solution studies⁶) and a distortion of the tertiary structure of the helix, although it is still closer to the B-DNA conformation. Several factors play a role in the stabilisation of the drug-DNA complex. The anthracycline is stabilised by electrostatic hydrogen bond and stacking π -bond interactions between the electron-deficient quinone-based chromophore and the electron-rich purine-pyrimidine bases. Hydrogen bonds play an important part in the stabilisation of the complex assisted by way of several water molecules and a solvated sodium cation. Indeed, an anthracycline lacking the hydroxyl group at C-9 on the right side of the ring-A is devoid of anticancer activity. Also, the hydrogen atom of the charged amino group is hydrogen bonded to O-2 of the thiamine base (T10) and two water molecules. Replacing the C-13 hydrogen atom with the hydroxyl group as for Adriamycin (**2**), this created⁷ additional hydrogen bonded interactions involving solvent media around the substituent. As this study⁵ included the charged aliphatic-amino spermine molecules close to the intercalation site, an important change in the bonding interaction of spermine and the complex was observed between daunomycin and Adriamycin.

ii. Unplanar chromophore-DNA complex

The dumbbell shaped anthracycline nogalamycin (**3**)⁷ was found to form a stable intercalative complex with DNA as revealed by X-ray⁷ and NMR spectroscopic⁸ studies. To accommodate intercalation of the nogalamycin chromophore, the DNA helix must 'open up', by transiently melting to allow entry of the bulky bicyclic amino sugar attached to ring-D. The DNA helix then elongates, translocating the base pairs in the approximate direction of the helical axis⁹. In another study¹⁰, a buckle of -25.4° in the C11-G2 base pair was observed. This would shed some light on the possibility of the target ring-D modified anthracycline (**4**) (R=H) intercalating with DNA and thereby test anticancer activity and intercalation theory. However, anthracyclines are

also known¹¹ to be enzymatically reduced to a radical species that form hydroxyl radicals (in the presence of molecular oxygen) to cause strand breaks in DNA and thereby cause inhibition of the replication process.

The antitumour ene-diyne antibiotics such as Dynemycin (**5**)¹² are known to inhibit cell replication by interfering with mitosis by causing single strand breaks in the DNA during spindle formation, by way of cyclisation of the ene-diyne bridge to a benzene biradical. On the basis of this, Adriamycin bearing the bridge on the A-ring could possess enhanced anticancer effectiveness by intercalating with DNA and causing single strand breaks by forming the benzene biradical, *in situ*. The benzene species is shown below; the radicals seen as yellow dots. The synthesis of such a compound would indeed be a highly challenging synthetic endeavour in the laboratory!

Other classes of anticancer drug-DNA interactions have been studied. For example, the image below represents the crystal structure of a double-stranded DNA decamer containing a cisplatin $[\text{Pt}(\text{NH}_3)_2]$ interstrand cross-link adduct¹³. Advances in other small molecule DNA-intercalators (including anthracyclines) was recently reviewed¹⁴.

A view of the idarubicin-D(CGATCG) complex¹⁵ is shown below (via RCSB) and intercalation is still being investigated¹⁶.
